Coalesced CAP: An Improved Technique for Frequency Assignment in Cellular Networks

Sasthi C. Ghosh, Bhabani P. Sinha, *Fellow, IEEE*, and Nabanita Das, *Senior Member, IEEE*

***Abstract*—This paper presents an elegant technique for solving the channel assignment problem (CAP) for second generation (2G) cellular mobile networks, where channel allocation is made on a quasi-fixed basis and all sessions are connection oriented. It first maps a given CAP P to a modified coalesced CAP P' on a smaller subset of cells of the network, which appreciably reduces the search space. This helps to solve the problem P' by applying approximate algorithms very efficiently, reducing the computing time drastically. This solution to P' is then used to solve the original problem P by using a modified version of the forced assignment with rearrangement (FAR) operation reported by Tcha *et al.* (*IEEE Trans. Veh. Technol.*, vol. 49, p. 390, 2000). The proposed technique has been tested on well-known benchmark problems. It has produced optimal solutions for all cases with an improved computation time. For instance, it needs only around 10 and 20 s (on an unloaded DEC Alpha station 200 4/233) to get an optimal assignment for the two most difficult benchmark problems 2 and 6, respectively, with zero call blocking, in contrast to around 60 and 72 s (on an unloaded Sun Ultra 60 workstation) reported by Ghosh *et al.* Moreover, as a by-product of this approach, there remain, in general, many unused or redundant channels that may be used for accommodating small perturbations in demands dynamically.**

***Index Terms*—Benchmark problems, cellular networks, channel assignment, fixed bandwidth, minimum span.**

I. Introduction

IN RECENT years, the number of mobile users has grown up rapidly, whereas the communication bandwidth for providing service to them has grown very moderately. Hence, the problem of using the radio spectrum efficiently to satisfy the customers' demands has become a critical research issue. This paper considers second generation (2G) cellular network systems, where it is assumed that the demands of the cells are known *a priori*, and the channels are to be allocated to the cells statically to cater sessions that are basically connection oriented. Here, the key factor is the reuse of radio spectrum in cells avoiding channel interference. Neglecting other influencing factors, we assume that channel interference is primarily a function of frequency and distance. A channel can simultaneously be used by multiple base stations if their mutual separation is more than the reuse distance, i.e., the minimum distance at which two signals of the same frequency do not interfere. In a cellular environment, reuse distance is usually expressed in units of number of cells. Based on that, three types of interference are generally taken into consideration: 1) cochannel interference, due to which the same channel is not allowed to be simultaneously assigned to a pair of cells that are not sufficiently far apart, 2) adjacent channel interference, for which adjacent channels are not allowed to be assigned to certain pairs of cells simultaneously, and 3) co-site interference, which implies that any pair of channels assigned to the same cell must be separated by a certain minimum distance in frequency. The task of assigning frequency channels to cells satisfying the frequency separation constraints with a view to avoiding channel interference and using as small bandwidth as possible is known as the channel assignment problem (CAP). In its most general form, CAP is equivalent to the generalized graph-coloring problem, which is a well-known NP-complete problem [2].

Earlier works on approximate algorithms for channel assignment can be broadly classified into two categories. For the first category of CAP, these approximate algorithms first determine an ordered list of all calls and then assign channels deterministically to the calls to minimize the required bandwidth [6], [16], [18], [20]. For the second category of CAP, given the bandwidth of the system, the approximate algorithms formulate a cost function, such as the number of calls blocked by a given channel assignment, and then tries to minimize this cost function [3]–[5], [10], [12], [13], [17], [19], [23]. The advantage of the first category of algorithms is that the derived channel assignment always fulfills all the interference constraints for a given demand, but it may be hard to find an optimal solution in case of large and difficult problems, even with quite powerful optimization tools. On the other hand, for the second category of algorithms, it may be impossible to minimize the cost function to the desired value of zero, in case of hard problems, with the minimum number of channels. In [9], the authors combined both of the above methods and proposed the combined genetic algorithm (CGA) that generates a call list in each iteration and evaluates the quality of the generated call list following the frequency exhaustive assignment (FEA) strategy.

In order to compare the performance of these algorithms for channel assignment, some well-known benchmark instances,

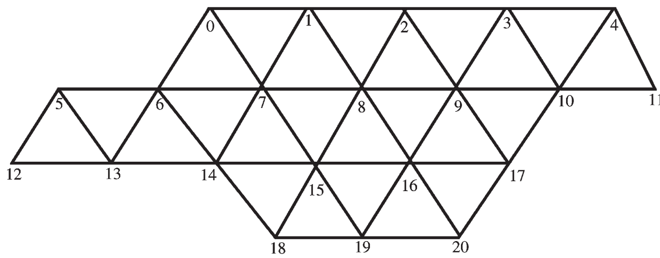

Fig. 1. Benchmark cellular network.

commonly known as Philadelphia benchmarks, are widely used in the literature [6], [7], [9]–[11], [13]–[18], [20]. These benchmarks are defined on a 21-node cellular network shown in Fig. 1. Here, each node represents a cell, and two nodes are connected by an edge, if the corresponding cells share a common boundary. The demands of the cells are represented by any one of the two nonhomogeneous demand vectors D_1 and D_2 shown in Table I. The column i in Table I indicates the channel demand from cell i corresponding to D_1 or D_2. These benchmark instances have been defined on the hexagonal cellular network assuming a two-band buffering restriction, i.e., interference does not extend beyond two cells from the call originating cell. It has been assumed that for avoiding channel interference the calls in the same cell should be separated by at least s_0 channels, and the calls in the cells that are distances of one and two apart should be separated by at least s_1 and s_2 channels, respectively. Table II shows the specifications of these eight problems (problems 1 through 8) in terms of the specific values of s_0, s_1, and s_2 for a two-band buffering system and the corresponding demand vector used for each of them.

Among the eight Philadelphia benchmark instances, it is relatively easier to derive the optimal solutions for all the problems except 2 and 6, because in all those six cases the required number of channels is primarily limited by the co-site interference constraint only. Most difficult is, however, to get the optimal solution for the other two Philadelphia instances—problems 2 and 6 [9], [18]. For example, the assignment algorithm given in [10] required 165 h of computing time for problem 6 on an unloaded HP Apollo 9000/700 workstation but producing only a nonoptimal solution with 268 channels (optimal solution requires only 253 channels). Later, however, the authors in [9] proposed an algorithm that provided optimal solutions for both problems 2 and 6 with a running time of 8 and 10 min, respectively, on the same workstation. Among later works, the frequency exhaustive strategy with rearrangement (FESR) algorithm in [11] and the randomized saturation degree (RSD) heuristic presented in [18] also produce only nonoptimal solutions to benchmark problems 2 and 6. However, combining their RSD heuristic with a local search (LS) algorithm, the authors in [18] were able to find an optimal solution for problem 2 but not for problem 6. Recently, an efficient heuristic algorithm has been proposed in [20], which also produced nonoptimal results for problems 2 and 6 with 463 and 273 channels, respectively. Most recently, given the concept of a critical block of the hexagonal cellular network, the authors in [21] proposed a novel algorithm that provides an optimal assignment for problems 2 and 6 with relatively less computation time than that in [9]. The critical block approach [21] requires only around a few seconds for optimal channel assignment of the other six benchmark instances on an unloaded Sun Ultra 60 workstation. For benchmark problems 2 and 6, however, the approach requires only around 60 and 72 s, respectively, on the same workstation. Hence, so far, the scheme reported in [21] has produced the best results in least time for all the benchmark problems.

In this paper, an elegant technique is presented for solving the second category of CAP, which first maps a given CAP P to a modified problem P' (coalesced CAP) on a small subset of cells of the network, offering a much reduced search space. This helps solving the problem P' by applying approximate algorithms more efficiently. This solution to P' is then used to solve the original problem P. However, based on the solution obtained for P', two possible situations may arise: 1) the solution to P derived from the solution to P' results in zero call blocking, i.e., it is an admissible solution for P or 2) if all requirements for P are not satisfied by the solution to P', resulting in call blocking. An algorithm is then presented that is a modified version of the forced assignment with rearrangement (FAR) operation reported in [11]. Application of this modified FAR (MFAR) operation to well-known benchmarks generates optimal results for all of them. Also, computation time is improved even over that of the critical block approach reported in [21]. Moreover, this approach results, in general, in some unused or redundant channels that may effectively be utilized to solve the perturbation-minimizing frequency assignment problem (PMFAP) [11] dynamically.

The problem is formulated in Section II. Section III describes the construction of coalesced CAP. The technique for solving the original problem is presented in Section IV. Section V shows the simulation results. Finally, concluding remarks are included in Section VI.

II. Problem Formulation

We use here the same model to represent a CAP as described in [1], [6], and [8]. This model is described by the following components:

1) a set X of n distinct cells with labels $0, 1, \ldots, n-1$;
2) a demand vector $W = (w_i)(0 \leq i \leq n-1)$, where w_i represents the number of channels required for cell i;
3) a frequency separation matrix $C = (c_{ij})$, where c_{ij} represents the minimum frequency separation requirement between a call in cell i and a call in cell j $(0 \leq i, j \leq n-1)$;
4) a frequency assignment matrix $\Phi = (\phi_{ij})$, where ϕ_{ij} represents the frequency assigned to call j in cell i $(0 \leq i \leq n-1, 0 \leq j \leq w_i - 1)$. The assigned frequencies ϕ_{ij}s are assumed to be evenly spaced and can be represented by integers ≥ 0;
5) a set of frequency separation constraints specified by the frequency separation matrix $|\phi_{ik} - \phi_{jl}| \geq c_{ij}$ for all i, j, k, l (except when both $i = j$ and $k = l$).

constraints	s_2	1	1	1	1	1	1	1	1
Demand vector		D_1	D_1	D_1	D_1	D_2	D_2	D_2	D_2

Based on this model, a CAP P can be characterized by the triplet (X, W, C). A given CAP can be typically represented by means of a graph G, where the k-th call to cell i is represented as a node v_{ik}, and the nodes v_{ik} and v_{jl} are connected by an edge with weight c_{ij} if $c_{ij} > 0$. This graph is referred to the CAP graph in [1]. Then, the channels are assigned to the nodes of the CAP graph in a specific order and a node will be assigned the channel corresponding to the smallest integer that will satisfy the frequency separation constraints with all the previously assigned nodes. It is evident that the ordering of the nodes has a strong impact on the required bandwidth. Suppose there are m nodes in the CAP graph, where m is the total requirement, i.e., $m = \sum_{i=0}^{i=n-1} w_i$. Therefore, the nodes can be ordered in $m!$ ways, and hence, for sufficiently large m, it is impractical to find the best ordering by an exhaustive search. Instead, more time efficient heuristics are necessary to find an optimal or near-optimal solution to the problem.

A frequency assignment Φ for P is said to be admissible if ϕ_{ij}s satisfy component 5 above for all i, j, where $0 \leq i \leq n-1$ and $0 \leq j \leq w_i - 1$. The span $S(\Phi)$ of a frequency assignment Φ is the maximum frequency assigned to the system. That is

$$S(\Phi) = \max_{i,j} \phi_{ij}.$$

Thus, the objective of the first category of CAP is to find an admissible frequency assignment with the minimum span $S_0(P)$, where $S_0(P) = \min\{S(\Phi) | \Phi \text{ is admissible for } P\}$. This class of assignment problem is known as the minimum span frequency assignment.

For the second category of CAP, we look for the channel assignment when the bandwidth B of the system is given, which may even be smaller than the required lower bound on bandwidth for the given problem. Depending on B, it may or may not be possible to satisfy all the channel demands of each cell unless B is sufficiently large. Thus, a solution to this variant of CAP may, in general, leave some blocked calls. However, the objective in this case is to minimize call blocking as far as possible. This class of assignment problems is known as the fixed bandwidth channel assignment. Suppose, due to the bandwidth constraint, only w'_i channels are assigned to cell i instead of w_i in an assignment $\Phi = (\phi_{ij})$ for P, where $w'_i < w_i$ for some or all i. Then, the frequency assignment Φ is said to be not admissible, and $b_i = (w_i - w'_i)$ (where $w'_i < w_i$) calls are blocked in the cell i by Φ. We represent the set of blocked calls by means of the vector $BL = (b_i)$. Then, the total blocking BL_{total} of the system is defined as

$$BL_{\text{total}} = \sum_{i=0}^{i=n-1} b_i.$$

Given the bandwidth B of the system, the objective of this fixed bandwidth formulation of CAP is to find Φ for P such that BL_{total} is as low as possible. We find a solution to this problem by using a coalesced CAP as explained below.

III. CONSTRUCTION OF A COALESCED CAP

For a given CAP P, initially the first category of algorithms is applied to find a solution assuming a single demand per cell. This solution is now used to construct the coalesced CAP P'. Here, the algorithm to generate a coalesced CAP P' from the given CAP P follows.

Algorithm Construct_Coalesced_Cap

Step 1: Define the CAP $P^* = (X^*, W^*, C^*)$ from the given CAP $P = (X, W, C)$ such that $X^* = X$, $C^* = C$, but $W^* = (w^*_i) = (1)$, i.e., $w^*_i = 1 \forall i$ $(0 \leq i \leq n-1)$. Note that P^* is nothing but P with the homogeneous single demand per cell.

Step 2: Find an admissible frequency assignment Φ^* for P^* applying a suitable algorithm of the first category (e.g., the algorithm GA in [22]). Let $a_0, a_1, \ldots, a_{z-1}$ be the z $(z \leq n)$ different channels assigned by Φ^*.

Example 1: To demonstrate this step, let us consider a practical assignment problem from Helsinki, Finland [5], [18], [20], to be referred later as problem 9. The example CAP $P = (X, W, C)$ has been formulated on a 25-cell system of nonhexagonal structure whose frequency separation matrix C and demand vector W are shown in Tables III and IV, respectively. The entry corresponding to the ith row and jth column in Table III, i.e., c_{ij}, represents the minimum frequency separation requirement between a call in cell i and a call in cell j $(0 \leq i, j \leq 24)$. The column i of the row D_3 in Table IV indicates the channel demand w_i from cell i. Next, the problem $P^* = (X^*, W^*, C^*)$ is derived from P (problem 9 defined above), where $X^* = X$, $C^* = C$, but $W^* = (w^*_i) = (1)$. Table V shows an admissible solution Φ^* for P^*, where column i indicates the channel assigned to cell i. Note that Φ^* needs $z = 8$ channels, namely, $a_0 = 0, a_1 = 1, \ldots, a_7 = 7$, respectively.

		65	66	57	72	61	50	46
		68	70	67		64	52	49
						69	56	54
							59	
$T_a \rightarrow$	7	9	9	9	8	10	11	10
$T_r \rightarrow$	7	9	9	9	8	10	11	10

Step 3: Construct the coalesced CAP $P' = (X', W', C')$ from Φ^* using the following four substeps.

Step 3.1: Let $Y(i)$ be the set of all cells where channel a_i has been assigned in Φ^*. Since every cell demands only one channel, $Y(i) \cap Y(j) = \text{NULL}$ for $i \neq j$. On the other hand, since Φ^* is admissible, $X^* = \cup_{i=0}^{i=z-1} Y(i)$.

Example 2: For the problem P^* in Example 1, the admissible assignment Φ^* is shown in Table V. Note that channel 0 has been assigned to cells 7, 13, 20, and 24. Hence, $Y(0) = \{7, 13, 20, 24\}$. Similarly, $Y(1) = \{4, 6, 18, 23\}$, $Y(2) = \{5, 10, 11, 16\}$, $Y(3) = \{2, 14\}$, $Y(4) = \{9, 19\}$, $Y(5) = \{0, 3, 17\}$, $Y(6) = \{1, 8, 15, 22\}$, and $Y(7) = \{12, 21\}$.

Step 3.2: Compute the maximum entry in C (the frequency separation matrix of P) for every pair of cells u and v, $u \in Y(i)$, $v \in Y(j)$, and denote it by $c'(a_i, a_j)$. That is

$$c'(a_i, a_j) = c'\left(Y(i), Y(j)\right) = \max_{u \in Y(i), v \in Y(j)} \{c_{uv}\}$$

where $0 \leq i, j \leq z - 1$.

Example 3: For the problem in Example 1, from Table III, we get $c'(Y(0), Y(1)) = c'(a_0, a_1) = 1$, i.e., 1 is the maximum among all c_{ij}s, where $i \in Y(0) = \{7, 13, 20, 24\}$ and $j \in Y(1) = \{4, 6, 18, 23\}$. All $c'(a_i, a_j)$s $(0 \leq i, j \leq 7)$ are shown in Table VI.

Step 3.3: Find the maximum weight among all cells in $Y(i)$, and denote it by $M(a_i)$. That is

$$M(a_i) = M(Y(i)) = \max_{j \in Y(i)} \{w_j\}$$

where $0 \leq i \leq z - 1$.

Example 4: For the problem in Example 1, the demands of each cell are given in Table IV. From this table, $M(Y(0)) = M(a_0) = 7$, i.e., 7 is the maximum demand among the cells in $Y(0) = \{7, 13, 20, 24\}$. Similarly, $M(a_1) = 9$, $M(a_2) = 9$, $M(a_3) = 9$, $M(a_4) = 8$, $M(a_5) = 10$, $M(a_6) = 11$, and $M(a_7) = 10$.

Step 3.4: Represent all the cells in $Y(i)$ by a single node $N(Y(i))$ of a weighted graph G', where the weight of a node $N(Y(i))$ is $M(Y(i))$. Connect nodes $N(Y(i))$ and $N(Y(j))$ by an edge with weight $c'(Y(i), Y(j))$ if $c'(Y(i), Y(j)) > 0$, and terminate.

This graph G' is termed as the coalesced CAP graph. The corresponding coalesced CAP $P' = (X', W', C')$ is represented by the following components:

1) a set $X' = (N(Y(i)))$ $(0 \leq i \leq z - 1)$ of z distinct nodes, where node $N(Y(i))$ represents the set $Y(i)$ in Φ^* of P^*;
2) a demand vector $W' = (M(Y(i)))$, where $M(Y(i))$ represents the weight of the node $N(Y(i))$ in G', $0 \leq i \leq z - 1$;
3) a frequency separation matrix $C' = (c'(Y(i), Y(j)))$, where $c'(Y(i), Y(j))$ represents the weight of the edge between nodes $N(Y(i))$ and $N(Y(j))$ in G', $0 \leq i, j \leq z - 1$;
4) a frequency assignment matrix $\Phi' = (\phi'_{ij})$, where ϕ'_{ij} represents the frequency assigned to call j in the node $N(Y(i))$ $(0 \leq i \leq z - 1, 0 \leq j \leq M(Y(i)) - 1)$;
5) a set of frequency separation constraints specified by the frequency separation matrix $|\phi'_{ik} - \phi'_{jl}| \geq c'(Y(i), Y(j))$ for all i, j, k, l (except when both $i = j$ and $k = l$). ■

Once P' is constructed as above, the objective is now to find an assignment Φ' for this P' with a given bandwidth B.

Example 5: The coalesced CAP $P' = (X', W', C')$ for the problem $P = (X, W, C)$ in Example 1 is given by $X' = (N(a_i))$, $0 \leq i \leq 7$, $W' = (7, 9, 9, 9, 8, 10, 11, 10)$, and C' is as given in Table VI.

Lemma 1: The given CAP P and the coalesced CAP P' are equivalent if $z = n$. For $z < n$, the total search space of P' is always less than that of P.

Proof: Clearly, if $z = n$, problems P and P' have the same number of nodes having the same weights, and $C = C'$. Hence, there is no reduction in search space after transferring P to P'.

As explained in Section II, the number of nodes and their demands in a CAP graph actually determine the total search space for a given CAP. Let the sum of demands on all cells for problems P and P' be $\mathcal{T}$ and $\mathcal{T}'$, respectively. Hence, the CAP graphs for P and P' will have $\mathcal{T}$ and $\mathcal{T}'$ nodes, respectively. If $z < n$, $\mathcal{T}'$ must be less than $\mathcal{T}$ because the sum of the demands of all the cells in $Y(i)$ has been replaced by the maximum of those to contribute to $\mathcal{T}'$. Hence, we have the proof. ■

IV. Proposed Technique for Solving the Original CAP From the Coalesced CAP

Transforming the original CAP $P = (X, W, C)$ to the coalesced CAP $P' = (X', W', C')$, we apply a suitable algorithm

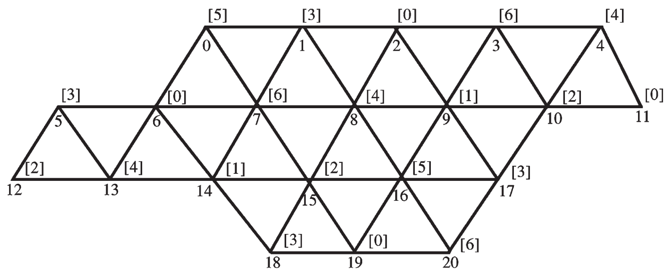

Fig. 2. Single-channel assignment of the benchmark problem 5.

of the second category of CAP to find a frequency assignment Φ' of P' with a view to minimizing the number of blocked calls BL_{total}. The assignment Φ' may or may not be admissible, depending on the available bandwidth B. Hence, to derive the required assignments for P, we consider the following two cases.

Case 1: Assignment Φ' is Admissible: In this case, an admissible frequency assignment for P can be derived by using Φ' by means of the following theorem.

Theorem 1: Given the problem $P = (X, W, C)$ and the bandwidth B, if the frequency assignments Φ' for P' are admissible, an admissible frequency assignment for P can be derived from Φ'.

Proof: To get an assignment of P from Φ', all the cells in $Y(i)$ $(0 \leq i \leq z-1)$ are assigned the same set of channels assigned to $N(Y(i))$ in Φ'. This assignment must satisfy the interference constraints because in P', $c'(Y(i), Y(j))$ is the maximum among all c_{ij}s in C, where $i \in Y(i)$ and $j \in Y(j)$. This assignment must also satisfy the demand vector $W = (w_i)$, since in P', $M(Y(i))$ is the maximum among all w_is in W, where $i \in Y(i)$. ■

When it is admissible, Φ' not only satisfies all the requirements of P but also provides some redundant channels. If cell i has been assigned w'_i channels while the requirement was w_i and $w'_i > w_i$, then $r_i = (w'_i - w_i)$ number of channels remains unused or redundant in cell i. This set of redundant channels is represented by the vector $R = (r_i)$. The total number of redundant channels R_{total} of the system is

$$R_{\text{total}} = \sum_{i=0}^{i=n-1} r_i.$$

Example 6: For the problem in Example 1, the derived problem P' has been completely described in Example 5 above. One solution to P' has been obtained by the algorithm in [9]

(a GA-based algorithm for the second category of CAP), as shown in Table VII, where entries in row T_a indicate the total number of channels assigned to each node, and those in row T_r indicate the total number of channels actually required for each node (in all subsequent tables, T_a and T_r will indicate the same meaning as mentioned here). In Table VII, the rows T_a and T_r are identical with the demand vector W' of P'. In other words, the frequency assignment of Table VII is admissible. The complete assignment following Theorem 1 has been shown

in Table VIII. Note that the same set of channels assigned to node $N(Y(0))$ has also been assigned to all the cells in $Y(0) = \{7, 13, 20, 24\}$. It is easy to verify that this assignment is also admissible for P. In addition, this assignment keeps five redundant channels in cell 3. Similarly, the redundant channels for other cells can be computed, and we get $R = (0,0,0,5,0,5,4,0,7,0,1,0,0,0,2,5,5,5,4,1,1,6,6,2,2)$ and $R_{\text{total}} = 61$.

Case 2: Assignment Φ' is not Admissible: In this case, the given bandwidth B is not enough to satisfy all the requirements for P'. Let us assume that Φ' satisfies the demand vector $W'' = (w''_i)$ instead of W', where $w''_i < w'_i$ for some or all i. From Φ', if we assign all the cells in $Y(i)$ $(0 \leq i \leq z-1)$ the same set of channels assigned to $N(Y(i))$, there will be, in general, some blocked calls in some cells, as well as some redundant channels in some other cells. We denote the blocked calls and redundant channels produced by this assignment as $BL = (b_i)$ and $R = (r_j)$, respectively, where $b_i = w_i - w''_i$, if $w''_i < w_i$ and 0 otherwise, and $r_j = (w''_j - w_j)$, if $w''_j > w_j$ and 0 otherwise. We then try to assign the blocked calls in BL by appropriately using these redundant channels in R and other available free channels by an approach similar to the FAR operation in [11]. For the sake of completeness, we briefly describe below the essential features of the FAR operation reported in [11].

Essence of FAR operation [11]: Let b_i be an unassigned requirement and Q denote the set of already assigned frequencies. Suppose for b_i there is no frequency available to be assigned without any conflict to the already assigned frequencies of Q. Then, FAR attempts to assign a frequency in L (where L is the given list of available frequencies) to satisfy the requirement b_i with minimum change or perturbation on the present assignment Q. The essence of FAR is to identify a minimal subset $S(b_i)$ of Q, where each requirement can be simultaneously reassigned with an alternative feasible frequency so that b_i can be assigned a frequency without conflict to the present assignment of Q. Let $B(b_i, f_i)$ denote the subset

of requirements in Q, which are conflicting, if we assign frequency f_i to requirement b_i. In other words, f_i becomes a feasible frequency for b_i if the frequency assignments for $B(b_i, f_i)$ are undone. To identify one $S(b_i)$, we examine a sequence of f_is such that each time a $B(b_i, f_i)$ is generated, we undo the corresponding portion of frequency assignment in Q and try to assign an alternative feasible frequency to each requirement of $B(b_i, f_i)$ by the unforced assignment (UA) operation. The UA operation finds the lowest frequency in L feasible to the present assignments in Q. If the frequency assignment of $B(b_i, f_i)$ is successfully made, $B(b_i, f_i)$ becomes $S(b_i)$ itself. In case such a frequency reassignment cannot be made for some $b_j \in B(b_i, f_i)$, one proceeds to identify $B(b_j, f_j)$ and attempts to assign an alternative feasible frequency to each $b_k \in B(b_j, f_j)$. Such $B(b_j, f_j)$s are blockers at the second depth level. Generalizing this, the FAR operation is encoded to render the so-called vth breadth-level and wth depth-level $(Bv{-}Dw)$ procedures. In $(Bv{-}Dw)$, we consider blockers only within the cardinality of v (i.e., $|B(t, f_i)| \leq v$) and limit the number of successive downward search to w. The complexity of FAR operation actually prohibits the direct implementation of this general $(Bv - Dw)$ procedure.

In our proposed algorithm, we have implemented $(B1-D1)$, $(B2-D1)$, and $(B1-D2)$ incorporating the concept of redundant channels as described above. We call this operation as the MFAR operation. This modification actually lies in the notion of a free channel to be assigned to an unassigned requirement, say, t in BL. We consider a channel to be free and suitable to be assigned to t even if it conflicts with the requirements of some other cells containing some redundant channels. However, when we choose such a channel for assigning it to t, we may need to undo some of the assignments in neighboring cells and adjust the assignments in other cells as well to keep the degree of perturbation (number of changes in the existing assignments) as low as possible, following the techniques similar to FAR operation [11].

Here, a formal description of the algorithm (Derive-Assignment (P, P')) to derive the solution to $P = (X, W, C)$ from the solution to P' follows.

Algorithm Derive-Assignment (P, P')

Step 1: Assign all the cells in $Y(i)$ $(0 \leq i \leq z-1)$ the same set of channels assigned to $N(Y(i))$ in Φ' of P'.

Remark 1: By similar arguments as in the proof of Theorem 1, this assignment satisfies the interference constraints as specified by C.

Step 2: Apply MFAR operation to minimize the blocked calls in $BL = (b_i)$ using the redundant channels in $R = (r_j)$ appropriately. ■

Example 7: To illustrate this step, we consider the Philadelphia benchmark problem 5 (Table II). We first construct P' for this problem as follows. A solution Φ^* of P^* is shown in Fig. 2, where the label $[\alpha]$ associated with a node indicates that a frequency α is assigned to that node. Only seven channels $(0, 1, \cdots, 6)$ have been assigned repeatedly in the assignment of Fig. 2, where $Y(0) = \{2, 6, 11, 19\}$, $Y(1) = \{9, 14\}$, $Y(2) = \{10, 12, 15\}$, $Y(3) = \{1, 5, 17, 18\}$, $Y(4) = \{4, 8, 13\}$, $Y(5) = \{0, 16\}$, and $Y(6) = \{3, 7, 20\}$. Corresponding frequency separations $c'(a_i, a_j)$ $(0 \leq i, j \leq 6)$ are shown in Table IX. We find $M(a_0) = 45$, $M(a_1) = 40$, $M(a_2) = 40$, $M(a_3) = 30$, $M(a_4) = 30$, $M(a_5) = 15$, and $M(a_6) = 25$. Therefore, $P' = (X', W', C')$ is given by $X' = (N(Y(i)))$, $0 \leq i \leq 6$, $W' = (45, 40, 40, 30, 30, 15, 25)$, and C' is as given in Table IX.

Now, to get Φ', we partition P' into several subnetworks with homogeneous weights, following the critical block approach reported in [21]. However, during the multiple weight

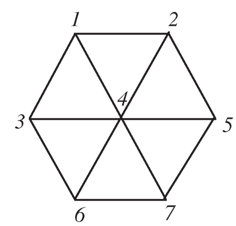

Fig. 4. Distance-2 clique of the hexagonal cellular network.

assignment, we consider the assignments with channels not exceeding the given bandwidth B only. One solution to P' as obtained by this approach has been shown in Table X. It follows that all the requirements for P' as given by $W' = (45, 40, 40, 30, 30, 15, 25)$ are not satisfied; this assignment results in four blocked calls in node $N(Y(5))$. In other words, the derived assignment is not admissible.

We now apply step 1 of the algorithm Derive-Assignment (P, P') to get the assignment for P from the solution to P' in Table X. The derived assignment for P has been shown in Table XI. Note that the same set of channels assigned to node $N(Y(0))$ has also been assigned to all the cells in $Y(0) = \{2, 6, 11, 19\}$. This assignment leaves four blocked calls $(15 - 11 = 4)$ in cell 16 and, at the same time, also produces many redundant channels in some other cells (e.g., cell 2 has 40 redundant channels).

We now apply step 2 of the algorithm Derive-Assignment (P, P') to get the assignment as shown in Table XII. Note that in the assignment of Table XI, there were four blocked calls in cell 16. However, MFAR operation finds that channels 0, 5, 10, and 15 can be assigned to cell 16 if the assignments of channels 0, 5, 10, and 15 from cells 2 and 19 are undone. Note that there are more than four redundant channels in both cells 2 and 19. The assignments of channels 0, 5, 10, and 15 in cell 16 have been underlined, and those of cells 2 and 19 have been marked by an asterisk $(*)$.

V. SIMULATION RESULTS

We have simulated the proposed coalesced CAP approach on all Philadelphia benchmark problems as well as on problem 9 defined above. Other than these benchmarks, we have also considered two other benchmarks defined on a 55-node cellular network [20] shown in Fig. 3. These two benchmarks have also been defined on a two-band buffering system where s_0, s_1, and s_2 are given as 7, 1, and 1, respectively. The demand vectors of these two problems (termed as Problems 10 and 11) are given by D_4 and D_5, respectively, as shown in Table XIII.

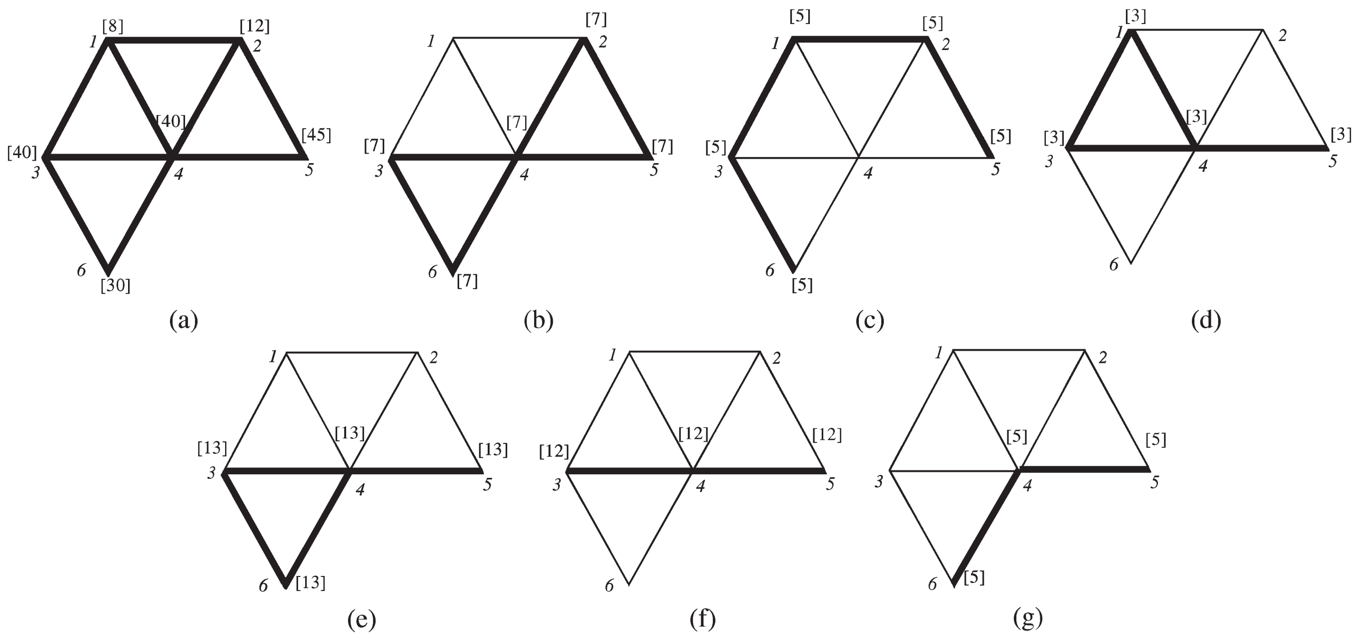

Fig. 5. Critical block and its homogeneous partitions.

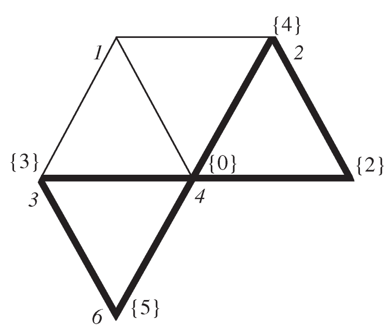

Fig. 6. Optimal partition assignment for partition P_1 in Fig. 5(b).

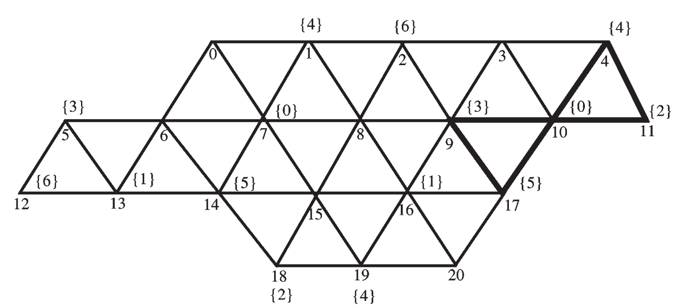

Fig. 7. Extension of partition P_1 of the critical block of problem 6.

The computation time needed to solve a given CAP following the proposed coalesced CAP technique is determined by the following three phases.

Phase 1: finding an admissible frequency assignment for P^* in step 2 of the Construct_coalesced_Cap algorithm by applying a suitable algorithm for the first category of CAP;

Phase 2: finding a frequency assignment Φ' of P' as derived in step 3 of the Construct_coalesced_Cap algorithm by applying a suitable algorithm for the second category of CAP;

Phase 3: the MFAR operation, if all requirements of P are not satisfied by Phase 2 above, i.e., the derived Φ' is not admissible.

It is to be noted that the computation time will depend on the performance of the algorithms chosen for phases 1 and 2 above.

For all the benchmark problems, except Philadelphia problems 2 and 6, we obtain assignments with zero call blocking if the given bandwidth B is equal to the respective lower bound of the problems. Also, significant improvement in computation time has been achieved as compared to earlier works, even to the critical block approach in [21]. Improvement is more significant for all such problems for which solutions to P' generate solutions to P, e.g., problems 1, 3, 4, 7, 9, and 10. For these problems, we need not execute the MFAR operation, and as a result, the computation time is of the order of a second on an unloaded DEC Alpha station 200 4/233. However, for other problems, e.g., problems 2, 5, 6, 8, and 11, all requirements for P are not satisfied by the solution to P', and we need to apply the MFAR operation to satisfy the remaining requirements. Out of these, for problems 5, 8, and 11, the solutions to P' generate a small number of call blocking in some cells and at the same time produce a large number of redundant channels in some other cells. As a result, the MFAR algorithm can easily accommodate these blocked calls by using redundant channels appropriately. For these problems, the computation time is around 3–4 s on the same workstation.

Most difficult is, however, to get the solution with zero call blocking for problems 2 and 6 by this approach when the given bandwidth B is equal to the respective lower bounds. For these benchmark problems, the solutions to P' generate a few blocked calls in some cells, whereas they produce only few redundant channels in some other cells. As a result, MFAR

fails to accommodate all these blocked calls. In the next section, we present a modification in our algorithm to reduce this problem.

A. Modification in Coalesced CAP Construction

Definition 1: Suppose $G = (V, E)$ is a cellular graph. A subgraph $G' = (V', E')$ of the graph $G = (V, E)$ is defined to be a distance-2 clique if every pair of nodes in G' is connected in G by a path of length at most 2 [1].

Example 8: Fig. 4 shows a distance-2 clique of a hexagonal cellular structure.

Definition 2: Given a cellular graph G with a demand vector W, and the set of all possible distance-2 cliques $\{G_j\}$, each with minimum bandwidth requirement B_j, the critical block CB_2 is that distance-2 clique, whose minimum bandwidth requirement is the maximum of all B_js.

While using the MFAR operation in the earlier section, we make an important observation that MFAR fails to accommodate mostly the blocked calls at the cells of a critical block. It appears that the assignment of the critical block is so tight that it becomes difficult to find alternative frequencies to be assigned to blocked calls existing in the critical block. This observation motivated us to a modification in the construction of coalesced CAP before we apply the MFAR operation as discussed below. We will see that with this modification Philadelphia problems 2 and 6 would finally require around 10 and 20 s, respectively, on the same platform to produce zero call blocking.

Algorithm Derive-Assignment (P, P')

Step 1: Following the approach in [21], find a critical block of P along with its homogeneous demand partitions and then assign the critical block. Let $P_1, P_2, \ldots, P_k$ be the k partitions with homogeneous weights $\alpha_1, \alpha_2, \ldots, \alpha_k$, respectively.

Example 9: For problem 6, the critical block is the distance-2 clique centered around node 10, i.e., consisting of nodes {3, 4, 9, 10, 11, 17}, which is isomorphic to G_2, as shown in Fig. 5(a). Fig. 5(b)–(g) shows the homogeneous partitions $P_1, P_2, \ldots, P_6$ (obtained through an integer programming formulation) with weights 7, 5, 3, 13, 12, and 5, respectively. In Fig. 5, the label $[\alpha]$ associated with a node indicates the demand of that node. After the partitioning of demands into homogeneous weights, the assignment of the critical block is obtained following an optimal ordering of partitions (see [21] for details). As an example, Fig. 6 shows an optimal partition assignment for the partition P_1 of Fig. 5(b).

Step 2: Define coalesced CAP $P' = (X', W', C)$, where X' is the subset of X containing the cells of the critical block, and W' is the actual demand of the cells of the critical block. (Here, the coalesced CAP is defined on the cells of the critical block.)

Step 3: Extend the assignment of each partition P_i $(i = 0, 1, \ldots, k)$ to consider the assignment of the remaining network. Combine all these assignments in the optimal ordering of the partitions $P_1, P_2, \ldots, P_k$. Compute the total blocking $BL_{\text{total}} = (b_i)$ in this combined assignment.

Remark 2: The assignment of each partition can be extended in many different ways. As a result, their combined assignment will generate different call blocking BL_{total} for different assignments, but the most important thing is that there never be blocked calls in the cells of X'. Our objective is to search heuristically to find such a combined assignment with minimal call blocking.

Step 4: Repeat step 3 for all possible assignments to obtain an assignment Φ_m with the minimal value of BL_{total}.

Step 5: Apply MFAR operation for reallocating the channels in Φ_m to minimize the blocked calls resulting from step 4 above. ■

Example 10: Consider the partition P_1 of the critical block of problem 6 and its optimal partition assignment shown in Figs. 5(b) and 6, respectively. One possible extension of the assignment of P_1 to consider the whole network has been shown in Fig. 7. This assignment may lead to call blocking in some cell but not in the critical block.

The required bandwidths from earlier works along with that from our proposed approach have been shown in Table XIV for the purpose of comparison. The row *Lower Bound* in Table XIV corresponds to the lower bound for each of the problems as reported in [21]. The derived channel assignments for the two most difficult problems, i.e., problems 2 and 6, are shown in Tables XV and XVI, respectively.

VI. CONCLUSION

We have presented an elegant technique for solving CAP, which is applicable even to a cellular network of nonhexagonal structure. The assignment is done for a given bandwidth B with a view to minimizing call blocking. The proposed technique is able to achieve the optimal solution for all the well-known benchmark problems when the given bandwidth B is equal to the lower bound of the corresponding problem. The required computation time has also been improved even over the critical block approach in [21]. Moreover, it can be further studied how unused or redundant channels provided by this approach can be utilized for accommodating small changes in demands dynamically.

ACKNOWLEDGMENT

The authors would like to thank the anonymous referees for their help in improving the presentation of this paper.

Sasthi C. Ghosh received the B.Sc. degree (Hons.) in mathematics from the University of Calcutta, Calcutta, India, in 1996, the Masters in Computer Applications degree from Jadavpur University, Calcutta, in 1999, and the Ph.D. degree in computer science from the Indian Statistical Institute, Calcutta, in 2004.

He is currently a Postdoctoral Fellow at the Institute of Mathematical Sciences, Chennai, India. His current research interests include mobile computing, wireless communication networks, distributed computing, *ad hoc* networks, and sensor networks.

Bhabani P. Sinha (M'84–SM'94–F'02) received the M.Tech. and Ph.D. degrees in radio physics and electronics from the University of Calcutta, Calcutta, India, in 1975 and 1979, respectively.

In 1976, he joined the Electronics Unit, Indian Statistical Institute, Calcutta, where he is currently a Professor and the Head of the Advanced Computing and Microelectronics Unit. He was a Visiting Faculty at the Southern Illinois University, Carbondale, from 1986 to 1987, the University of Central Florida, Orlando, in 1998, and Clemson University, Clemson, SC, from 2001 to 2002. He has published more than 100 archival research papers in the areas of computer architecture, fault diagnosis, graph algorithms, interconnection networks, parallel processing, and mobile computing. His current research interests include areas of parallel architectures and algorithms and mobile computing.

Dr. Sinha is a Fellow of the Indian National Academy of Engineering, National Academy of Sciences, India, the West Bengal Academy of Science and Technology, India, and the Institution of Electronics and Telecommunication Engineers, India. He was an Alexander von Humboldt Fellow of Germany from 1979 to 1981 and from 1990 to 1991. In 2000, he was the Indian Space Research Organization Chair Professor at the Indian Institute of Technology, Kharagpur, India.

Nabanita Das (M'99–SM'03) received the B.Sc. degree (Hons.) in physics and the B.Tech. degree in radio physics and electronics from the University of Calcutta, Calcutta, India, in 1976 and 1979, respectively, and the M.E. degree in electronics and telecommunication engineering and the Ph.D. degree in computer science from Jadavpur University, Calcutta, in 1981 and 1992, respectively.

Since 1986, she has been with the Advanced Computing and Microelectronics Unit, Indian Statistical Institute, Calcutta. She visited the Department of Mathematik and Informatik, University of Paderborn, Germany, under the INSA scientists' exchange program. Her research interests include parallel processing, interconnection networks, wireless communication, and mobile computing.
